Finding useful questions:

on Bayesian diagnosticity, probability, impact, and information gain

Abstract

Several norms for how people should assess a question's usefulness have been proposed, notably Bayesian diagnosticity, information gain (mutual information), Kullback-Liebler distance, probability gain (error minimization), and impact (absolute change). Several probabilistic models of previous experiments on categorization, covariation assessment, medical diagnosis and the selection task are shown to not discriminate between these norms as descriptive models of human intuitions and behavior. Computational optimization found situations in which information gain, probability gain, and impact strongly contradict Bayesian diagnosticity. In these situations, diagnosticity’s claims are normatively inferior. Results of a new experiment strongly contradict the predictions of Bayesian diagnosticity. Normative theoretical concerns also argue against use of diagnosticity. It is concluded that Bayesian diagnosticity is normatively flawed and empirically unjustified.
Finding useful questions:

on Bayesian diagnosticity, probability, impact, and information gain

When learning the meaning of a new word, diagnosing a patient’s illness, interviewing job candidates, or testing scientific hypotheses, choice of questions (experiments, tests, queries) is critical. Whether people can identify useful questions, and what exactly constitutes a useful question, are central problems in theories of human cognition. Popper’s (1959) falsificationist philosophy of science and Piaget and Inhelder's (1955/1958) experimental research inspired Wason's (1960, 1966) 2-4-6 task, which was designed to be a miniature scientific problem. Wason suggested that success on that task required "a willingness to attempt to falsify hypotheses" (p. 139). However, many subjects had difficulty devising tests to falsify their working hypotheses, a pattern sometimes called "confirmation bias" (Wason & Johnson-Laird, 1972, cited in Mynatt, Doherty, & Tweney, 1977; reviewed by Klayman, 1995). Many recent researchers have distanced themselves from the falsificationist view, and suggested that differentiation of plausible hypotheses is normatively a better goal than falsification of the working hypothesis. Several of these researchers have described evidence-acquisition situations in a probabilistic framework (Trope & Bassok, 1982, 1983; Fischoff & Beyth-Marom, 1983; Baron, 1981, cited in Baron, 1985, pp. 130-167; Skov & Sherman, 1986; Oaksford & Chater 1994, 2003).

An advantage of the probabilistic approach is the ability to differentiate the following components:

1. A probabilistic belief model with a set of hypotheses, a prior probability of each, and a set of possible questions (or experiments, queries, or tests) to differentiate between them;

2. A sampling norm to quantify the expected usefulness of each possible question,
relative to a probabilistic belief model;

3. A method to update beliefs according to a test’s outcome.

In models of sequential tasks, in which the first question’s answer is known before the second question is asked, an additional component, to check whether a stopping criterion has been reached, is also needed. (Similar accounts appear in Box & Hill, 1967; Fischoff & Beyth-Marom, 1983; Over & Jessop, 1998; and Zimmerman, 2000.) Most experimental research in this area (Table 1) assesses the adaptiveness of information-gathering behavior by considering whether people choose highly useful queries, as identified by a particular sampling norm. The goal of the present paper is to illuminate differences between sampling norms (component 2) by holding constant both probability belief models (component 1) and the method of belief updating (component 3).

In this paper, the intuitive scientist metaphor as outlined above is used as a descriptive model of human cognition, and Bayes’ (1763) theorem is used to update beliefs. Use of normative models as descriptive models, or to facilitate development of descriptive models, is a familiar research strategy (Anderson’s 1990, 1991, rational analysis; Brunswik’s, 1952, molar analysis; Peterson & Beach, 1967; Marr, 1982; Viswanathan, et al., 1999; Oaksford & Chater, 2001; McKenzie, 2003; Baron, 2004). However, Kuhn (1989, 2000) discusses both the usefulness and limitations of the normative intuitive scientist metaphor as a descriptive model of human cognition. It has also been suggested that humans change their beliefs to a lesser extent than predicted by Bayes’ (1763) theorem, perhaps by using a conservative Bayesian form of belief revision (Edwards, 1968). Setting these issues aside enables the present paper to focus on the relative normative and descriptive justification of several sampling norms in the psychological literature, each of which explicitly describes what makes a question (experiment,
query, or test) useful.

From a mathematical standpoint, method of belief revision (Bayesian or other) and choice of sampling norm (to assess possible questions’ expected usefulness) are completely independent of each other. This notwithstanding, some researchers have implied that Bayesian diagnosticity is the only theoretically (normatively) defensible, or the only Bayesian, sampling norm. For instance, Slowiaczek et al. (1992) stated “according to Bayes’ theorem, the diagnosticity [usefulness] of an answer or datum, D, depends on the likelihood ratio,” (p. 393), e.g. on that answer’s Bayesian diagnosticity. (Similar statements appear in Beyth-Marom & Fischoff, 1983, p. 1193; Fischoff & Beyth-Marom, 1983, pp. 240-241; Bassok & Trope, 1983-1984, p. 200; and Doherty, et al., 1996, p. 644.) Evans and Over (1996) stated log diagnosticity would be “much more satisfactory as a normative standard” than information gain (p. 358). Good (1975) simply said diagnosticity “was central to my first book (1947/50) and also occurred in at least 32 other publications … . What I say thirty-three times is true” (pp. 52-53).

Yet several norms have been proposed for evaluating the usefulness of a question (or test or experiment) in probabilistic evidence-gathering situations. Prominent proposals include information gain, Kullback-Liebler distance, impact (absolute change), probability gain (minimal error), Bayesian diagnosticity, and log diagnosticity (Table 1). The literature to date, however, does not make clear (1) what norms best describe human behavior, (2) when the norms disagree, or (3) whether some norms are theoretically (normatively) better motivated than others.

The rest of this paper is structured as follows. Each sampling norm is explicitly defined below. (Appendix 1 provides a more intuitive scenario and example calculations.) Prior experimental evidence-acquisition research is reanalyzed to examine the extent to which earlier researchers’ conclusions depend on the sampling norm used. New simulations demonstrate that
the sampling norms can disagree with each other, and that this disagreement occurs in a variety of statistical environments. Further simulations identify particularly strong cases of disagreement between norms. Those limiting cases are used to design a definitive experiment, to address whether diagnosticity and log diagnosticity are plausible descriptive psychological models of human intuitions. Finally, theoretical objections to diagnosticity and log diagnosticity are discussed, and important issues for future research are outlined.

[insert Table 1 about here]

The sampling norms

There is a conceptual distinction between \textit{disinterested} utility functions for evidence acquisition, and \textit{situation-specific} utility functions, for situations with unique reward structures (Lindley, 1956; Box & Hill, 1967; Baron & Hershey, 1988; Kirby, 1994; Chater, Crocker, & Pickering, 1998; Chater & Oaksford, 1999). Disinterested utility functions are useful for information gathering, where no immediate action is required; Chater, Crocker, and Pickering liken them to pure scientific research. Situation-specific utility functions are appropriate when making the best decision is more important than believing the correct hypothesis. However, the same mathematical framework can be used in both cases (Savage, 1954, pp. 105-119; Raiffa, 1968). Each norm discussed in this paper—diagnosticity, log diagnosticity, information gain, KL distance, probability gain, and impact—can be thought of as a subjective utility function for evidence acquisition. The norms give different definitions of an individual \textit{answer}'s usefulness. However, all of the norms define a \textit{question}'s usefulness as the \textit{expected usefulness} of its possible answers, averaged according to the probability of each possible answer occurring.

A technical definition of each norm is given below. Appendix A provides a more intuitive treatment, in the context of the Vuma probability model, with example calculations and further
discussion. In this paper's notation capital letters represent random variables; lowercase letters represent specific values that those random variables can take. \( Q \) is a question, query, test, or experiment, whose results are unknown; \( q_j \) are specific answers, or experiment results; \( C \) is the unknown category, or hypothesis; and \( c_i \) are particular categories, or hypotheses.

**Bayesian diagnosticity**

Good (1950, 1975, 1983) introduced the concept of diagnosticity. He called an answer’s diagnosticity the “weight of evidence” and a question’s diagnosticity the “expected weight of evidence.” Explicit use of the term diagnosticity in this context appeared at least as early as Edwards (1968, pp. 25-27).¹ Diagnosticity relates to the likelihood ratio of particular data given two categories:

\[
\text{diagnosticity}(q_j) = \max \left( \frac{P(q_j \mid c_i)}{P(q_j \mid c_0)}, \frac{P(q_j \mid c_0)}{P(q_j \mid c_i)} \right), \quad \text{and}
\]

\[
\text{diagnosticity}(Q) = \sum_{q_j} P(q_j) * \text{diagnosticity}(q_j).
\]

(Max(a,b) denotes the larger of a and b. If equal pick randomly.)

**Log₁₀ diagnosticity**

The set of researchers using log diagnosticity is virtually the same as the set of researchers using diagnosticity. Some researchers first introduce diagnosticity, then use log diagnosticity for their calculations, without addressing whether those sampling norms may disagree, or giving a rationale for preferring one or the other (Evans & Over, 1996; McKenzie & Mikkelsen, in press). But their expectations are not equivalent: a question's diagnosticity cannot be derived from its log diagnosticity, or vice versa. Base 10 (“log₁₀ diagnosticity”) will be used in this paper; constant positive multiples convert between bases. Specifically:
Finding useful questions

\[
\log_{10} \text{diagnosticity}(q_j) = \log_{10} \max \left( \frac{P(q_j \mid c_1)}{P(q_j \mid c_0)} \cdot \frac{P(q_j \mid c_0)}{P(q_j \mid c_1)} \right) = \text{abs} \left( \log_{10} \frac{P(q_j \mid c_1)}{P(q_j \mid c_0)} \right), \quad \text{and} \\
\log_{10} \text{diagnosticity}(Q) = \sum_{q_j} P(q_j) \cdot \log_{10} \text{diagnosticity}(q_j).
\]

It should be emphasized that the two above formulations of an answer \(q_j\)'s \(\log_{10}\) diagnosticity, one taking the maximum likelihood ratio, the other taking an absolute log likelihood ratio, are identical. Diagnosticity and log diagnosticity are both infinite for an answer \(q_j\) that eliminates a category (hypothesis) by setting its posterior probability to 0. The descriptive psychological claim is that such an answer, or a question \(Q\) with some probability of it, is infinitely useful.

**Information gain**

One way to measure a question's usefulness is by quantifying its expected reduction in uncertainty, or information gain, with respect to the true hypothesis, or category. Lindley (1956), Box (1967), and Fedorov (1972) quantified this idea explicitly, using Shannon's (1948) entropy to measure uncertainty. Good (1950, pp. 74-75) also alluded to the possibility of using a sampling norm based on Shannon entropy. Baron (1985, pp. 150-151; citing Marschak, 1974) suggested that using information gain would be appropriate in rare situations only, such as when maximizing data transmitted through a telephone line. Outside the realm of cognitive tasks, information gain has been employed to model development of visual neurons (Ruderman, 1994; Ullman, Vidal-Naquet, & Sali, 2002) and auditory neurons (Lewicki, 2002), and to set camera parameters in computer vision (Denzler & Brown, 2002). This paper measures information with base 2 logarithms (bits); one bit equals \(\log_2 2 = 0.6931\) nats of information. The information gain in \(Q\) is the mutual information between \(C\) and \(Q\) (Cover & Thomas, 1991):

\[
I(C, Q) = H(C) - H(C \mid Q),
\]

where
\[ H(C) = \sum_{c_i} P(c_i) \cdot \log_2 \frac{1}{P(c_i)}, \] the initial entropy in \( C \),

\[ H(C \mid Q) = \sum_{q_j} P(q_j) \cdot H(C \mid q_j), \] the conditional entropy in \( C \) given \( Q \), and

\[ H(C \mid q_j) = \sum_{c_i} P(c_i \mid q_j) \cdot \log_2 \frac{1}{P(c_i \mid q_j)}, \] the entropy in \( C \) given a particular answer \( q_j \).

**Kullback-Liebler distance**

A question’s usefulness could also be quantified as the amount that its answer is expected to change one’s beliefs. Kullback-Liebler distance (Kullback & Liebler, 1951; Cover & Thomas, 1991) provides one means to measure the change from prior beliefs about the true category, \( C \), to posterior beliefs after a particular question is answered:

\[
KL \text{ distance}(q_j) = \sum_{c_i} P(c_i \mid q_j) \cdot \log_2 \frac{P(c_i \mid q_j)}{P(c_i)}, \text{ and}
\]

\[
KL \text{ distance}(Q) = \sum_{q_j} P(q_j) \cdot \sum_{c_i} P(c_i \mid q_j) \log_2 \frac{P(c_i \mid q_j)}{P(c_i)}.
\]

In this paper, KL distance and information gain are equivalent, because they give identical measures of a question’s usefulness (Oaksford & Chater, 1996). (Table A1 illustrates that they give different statements of particular answers’ usefulness.)

**Probability gain**

Baron (1981, cited in Baron, 1985) suggested this norm as a special case of Savage's (1954, chap. 6, pp. 105-119) analysis of the value of observations, in which the inquirer assigns the same utility to any correct guess, and lower, equal utility to any incorrect guess. Assuming that the most probable category is chosen after a question’s answer is obtained, it’s possible to calculate how much asking a particular question improves the expected probability of making a
correct guess, the question’s probability gain. Maximizing probability gain is equivalent to
minimizing probability of error, a common criterion in computer science, as well as to
maximizing probability of making a correct decision. Specifically:

\[
\text{probabilityGain}(q_j) = \max_{c_i} P(c_i | q_j) - \max_{c_i} P(c_i), \text{ and }
\]

\[
\text{probabilityGain}(Q) = \left( \sum_{q_j} P(q_j) \cdot \max_{c_i} P(c_i | q_j) \right) - \max_{c_i} P(c_i).
\]

**Impact (absolute change)**

Impact is based on the idea that answers \(q_j\) that change beliefs are useful. In this respect
impact is similar to KL distance; however, it is based on a different measure of belief change.
Klayman and Ha (1987, pp. 219-220) and Nickerson (1996), discussing belief models with two
hypotheses, suggested measuring a particular answer's impact on an individual hypothesis as
\(\text{abs}(P(\text{hypothesis} | \text{answer}) - P(\text{hypothesis}))\); or, in present notation, \(\text{abs}(P(c_i | q_j) - P(c_i))\). If a
belief model contains exactly two hypotheses, as Nickerson noted, then a particular answer has
the same impact on each hypothesis. The present paper generalizes impact to situations with
multiple categories or hypotheses:

\[
\text{impact}(q_j) = \frac{1}{n} \sum_{c_i} \text{abs}(P(c_i | q_j) - P(c_i)), \text{ where } n \text{ is the number of categories } c_i, \text{ and }
\]

\[
\text{impact}(Q) = \sum_{q_j} P(q_j) \cdot \frac{1}{n} \sum_{c_i} \text{abs}(P(c_i | q_j) - P(c_i)).
\]

Slowiaczek et al. (1992, p. 402) reported that many subjects used the heuristic strategy of asking
about the feature with the maximal difference in feature probabilities, \(\text{abs}(P(\text{feature} | c_i) -
P(\text{feature} | c_j))\). It is presently shown that this strategy is not merely heuristic, but exactly
implements impact.\(^2\) If prior probabilities of two hypotheses are equal, impact and probability
gain are identical. Several models in the literature meet this condition (Slowiaczek et al., 1986; Skov & Sherman, 1992; Oaksford & Chater, 1994, 1998, 2003; Nickerson, 1996). (After an answer has been obtained, posterior probabilities of two hypotheses—which become priors for purposes of evaluating successive questions—will in general no longer be equal.)

Properties of the sampling norms

The psychological plausibility of claiming that subjective utility is infinite is questionable, so it is of interest to note whether each norm is finite. Similarly, it has been argued (Evans & Over, 1996) that it is psychologically implausible that an answer that changes beliefs can have negative utility. It is thus useful to note which norms are nonnegative. Finally, is the usefulness of obtaining two pieces of data (answers $q_1$ and $q_2$) simultaneously the sum of the usefulness of obtaining each datum separately? Intuitively, it seems that if two data in effect cancel each other out, such that posterior beliefs after obtaining both of them are the same as prior beliefs, those data were useless. Under which sampling norms is this the case? Table 2 lists which of these properties each sampling norm satisfies.

Prior research and the descriptive plausibility of each norm

Most research that assesses people’s faculties at identifying useful questions has used a single sampling norm to calculate each question’s usefulness. This raises the possibility that using other normative models would result in different conclusions. To what degree do earlier researchers' conclusions about people’s sensitivity to questions’ usefulness depend on the specific sampling norm used? This section considers several belief models, each with specific hypotheses, prior probabilities, and available questions. For each belief model, the usefulness of each question is computed using diagnosticity, information gain-KL distance, probability gain,
and impact. Because "the complexity of any real decision problem defies complete explicit description" (Savage, 1954, p. 107), the probability models below reflect simplified experimental tasks. For instance, although Baron, Beattie, and Hershey (1988) studied a simple case of medical diagnosis, extension of that analysis to actual medical decision making is not straightforward (Cohen, 1996; Baron, 1996). Nor is it straightforward to predict how subjects will interpret an experimental task (McKenzie, Wixted, & Noelle, 2004). On Wason’s selection task, there are several proposed probability models. An evenhanded approach, for the present paper, is to exactly implement the original researchers' belief model, in each experiment considered.

Two-category, binary-feature tasks. Skov and Sherman (1986) and Slowiaczek et al. (1992, experiments 3a and 3b) designed a task to be a case of miniature scientific inference, but in which appropriateness of a particular belief model was clear. Subjects were told the distribution of gloms and fizos, the two creatures on planet Vuma, and the distribution of various binary features within gloms and fizos. Subjects were asked to indicate which features they would ask about, to determine whether a novel creature were a glom or fizo. Skov and Sherman and Slowiaczek et al. used diagnosticity or log diagnosticity to measure the usefulness of questions. In Skov and Sherman's experiment, as many as 5 high diagnosticity questions could be chosen: 68% of the 66 subjects chose 5 high diagnosticity questions; an additional 18% chose 4 high diagnosticity questions. In Slowiaczek et al.'s experiment 3a, a single question was selected; 98% of subjects (196 of 199) chose a high diagnosticity question.

Do Skov and Sherman’s (1986) or Slowiaczek et al.’s (1992, experiment 3a) results depend on using diagnosticity or log diagnosticity to measure the usefulness of questions? In the present analysis, each question’s usefulness was calculated using information gain-KL distance,
probability gain, impact, diagnosticity and log diagnosticity. All norms agree with Skov and
Sherman’s high>medium>low ordering, and with Slowiaczek et al’s high>low ordering, of the
usefulness of each question (Table 3). This corroborates the earlier findings that people tend to
select reasonable questions. But neither experiment's behavioral results differentiate the relative
plausibility of the sampling norms under consideration as descriptive models.

[insert Table 3 about here]

Slowiaczek et al. (1992, experiment 3b) also sought to address whether people prefer
questions with extreme feature probabilities; e.g. wearing a hula hoop (Hula), present in 90% of
gloms and 55% of fizos; versus drinking iced tea (Drink), found in 65% of gloms and 30% of
fizos. The intent was to hold usefulness constant while modifying the extremity of feature
probabilities (Table 4) in a pair of questions. Unfortunately, the stimuli confounded extremity
with several sampling norms, such that the questions with more extreme feature probabilities
also had higher diagnosticity, log diagnosticity, and information gain-KL distance. Impact and
probability gain were indifferent between the two questions in each pair. Slowiaczek et al.’s
behavioral results were that on average, the feature with higher diagnosticity, log diagnosticity,
and information gain-KL distance was chosen around 60% of the time (chance would be 50%). It
is difficult to make strong inferences about the sampling norms from this result.

[insert Table 4 about here]

*Medical diagnosis.* Baron, Beattie, and Hershey (1988), experiments 4, 5, and 6, asked
subjects to rate the usefulness of several medical tests. The task instructions described a situation
in which probability gain would be the most obviously justifiable measure. Only one test could
be conducted before diagnosing and treating the disease. Diseases were described abstractly, as
diseases A, B, and C; their prior probabilities were 0.64, 0.24, and 0.12, respectively. Thus the
diseases were presumably equally problematic, if untreated, and equally treatable. Subjects were given the conditional probabilities that each of several tests would come out positive or negative, given each disease.\textsuperscript{5}

Subjects rated each test’s usefulness on a 0-100 scale “where 0 means the test is worthless and should not be done and 100 means the test would remove all doubt about which disease the patient has” (p. 101). Baron et al. found that subjects were generally sensitive to the relative usefulness of each test, as measured with probability gain. However, subjects consistently gave positive ratings to some tests that were useless, as calculated by probability gain. Baron et al. referred to this tendency as information bias.

Could the idea that subjects were making use of a sampling norm besides probability gain better explain Baron et al.’s (1988) data? To address this, the probability gain, impact, and information gain-KL distance of each test were computed (Table 5 and Table 6). Impact and information gain-KL distance agree with subjects that some zero probability gain tests are useful (tests 3-8 in experiment 4). In other words, if impact or information gain were to be deemed appropriate normative models of this task, information bias would largely disappear. Overall, however, while subjects’ ratings correlate highly with each sampling norm, there is no clear pattern wherein a particular sampling norm best accounts for responses (Table 7).

The abstract selection task. In a typical version of this task, introduced by Wason (1966, 1968), a subject is shown the top faces of four cards, showing A, 2, K, and 3. The subject is asked what cards would need to be flipped to falsify the rule that \textit{if a card has an A on one side,}
it has a 2 on the other side. Wason intended the selection task to be a deductive logical task, in which the 2 card and the K card would be useless. But very few subjects (seldom 10%) select just the A and 3 card (Stanovich & West, 1998); most subjects do select the 2 card, which Wason took to be a mistake. Over several decades of subsequent study involving around 1000 experimental subjects, the ordering of the most frequently selected cards has been A>2>3>K (Oaksford & Chater, 1994).

Oaksford and Chater (1994, 1998, 2003) introduced probabilistic, rather than logical, models of the selection task and proposed that subjects choose cards to maximize information gain with respect to their beliefs, rather than to falsify a particular hypothesis. There has been extensive debate about this approach (Evans & Over, 1996; Laming, 1996; Almor & Sloman, 1996; Oaksford & Chater, 1996, 1998, 1999; Over & Jessop, 1998), and other probabilistic models have also been proposed (e.g. Kirby, 1994; Klauer, 1999; Hattori, 2002). However, novel predictions have been tested behaviorally (e.g. Oaksford, Chater, & Grainger, 1999), in turn improving the model. Oaksford & Chater’s (2003) belief model includes two hypotheses: a dependence hypothesis, that every card with an A on one side does have a 2 on the other side; and an independence hypothesis, that A, K, 2, and 3 are assigned independently, with the constraint that each card has a letter on one side and a number on the other side. The model requires four parameters: probability of the dependence hypothesis, overall P(A), overall P(2), and probability of an error under the dependence hypothesis, under which A is paired with 3. The general constraints specified by Oaksford & Chater are that A’s and 2’s are rare and that the combination of parameters lead to a valid probability distribution under the dependence hypothesis (Over & Jessop, 1998, explicitly specify these constraints). Among other results, Oaksford and Chater found that the ordering of the information gain of each card, A>2>3>K,
matched card selection frequencies.

Would sampling norms other than information gain provide similar results? Oaksford and Chater’s (2003) model was implemented here, fixing $P(\text{dependence hypothesis})=0.5$, $P(\text{error})=0.1$, $P(\text{A})=0.22$ and $P(\text{2})=0.27$. Each norm gave the same ordering (Table 8), suggesting that at this level of analysis, the model does not differentiate the sampling norms under consideration. Would other parameter settings strongly differentiate the norms? If $P(\text{error})=0$, both diagnosticity and log diagnosticity rate the A and 3 cards as infinitely useful. This is because if $P(\text{error})=0$, each of these cards offers a chance of eliminating the dependence hypothesis, which diagnosticity and log diagnosticity consider infinitely useful. Diagnosticity and log diagnosticity are indifferent to the relative probability of eliminating a hypothesis when selecting the A or 3 card in this case. If $P(\text{error})=0.01$, diagnosticity rates the A and 3 cards as most useful; log diagnosticity rates the A and 2 cards as most useful. To summarize: if subjects believe $P(\text{error})$ is very low, diagnosticity and/or log diagnosticity contradict abstract selection task data. Information gain and impact-probability gain maintain the $\text{A}>\text{2}>\text{3}>\text{K}$ ordering when $P(\text{error})=0.01$ or 0. A further note is that Evans and Over (1996) objected to information gain per se, but not to Oaksford and Chater's probability model. Present results show that a sampling norm as intuitive as probability gain or impact could be used.

[insert Table 8 about here]

**Covariation assessment.** How are variables related to each other? Inhelder and Piaget's studies (1955/1958) set a foundation for research in several areas. This section focuses on covariation assessment (Inhelder & Piaget, 1955/1958; Smedslund, 1963; Peterson & Beach, 1967; McKenzie, 1994). A typical task involves two binary variables: $X$ (e.g., glom or not) and $Y$ (hulaWorn or not). Each individual observation falls in one cell of a matrix with four cells: cell
A, glom wearing a hula hoop; B, glom not wearing a hula hoop; C, fizo wearing a hula hoop; or D, fizo not wearing a hula hoop. Subjects frequently are shown a matrix with counts of the number of individuals in each of those four cells. Which cell’s observations are the most informative with respect to the goal of determining whether the variables $X$ and $Y$ covary? Most normative models treat the four cells as equally useful. Yet over several experimental manipulations (reviewed in McKenzie & Mikkelsen, in press), subjects treat A as most useful, and D as least useful, with B and C in between: $A > B \approx C > D$. This differential evaluation has been considered suboptimal.

McKenzie and Mikkelsen (in press) proposed that subjects may be approaching covariation assessment tasks as inferential tasks, and using their prior beliefs to interpret the tasks. For instance, subjects may have the goal of finding out which of two hypotheses is true: $h_1$, that there is a moderate correlation between $X$ and $Y$, or $h_0$, that $X$ and $Y$ are independent. Each hypothesis specifies the probability that an observation will fall in each of the cells A through D. Presence of $X$ (glom) and $Y$ (hulaWorn) are each rare (10% probability under both $h_1$ and $h_0$) in the model, corresponding to several researchers’ findings that subjects usually assume rarity in related tasks (Anderson & Sheu, 1995; McKenzie & Mikkelsen, 2000; McKenzie, Ferreira, Mikkelsen, McDermott, & Skrable, 2001; Oaksford & Chater, 2003). McKenzie and Mikkelsen calculated the $\log_2$ diagnosticity of an observation in each cell, relative to their probability model. McKenzie and Mikkelsen's model gave the ordering $A > B = C > D$, providing a rational explanation of one of the main covariation assessment research findings. In the present analysis, McKenzie and Mikkelsen’s probability model was implemented, and each cell’s usefulness was calculated, relative to information gain, KL distance, probability gain, impact, diagnosticity, and $\log$ diagnosticity. All sampling norms agree on the $A > B = C > D$ ordering. This result bolsters
McKenzie and Mikkelsen’s conclusion that subjects’ behavior is justifiable, but does not provide evidence against any sampling norm as a descriptive model of subjects’ behavior.

Do the sampling norms ever disagree?

The previous section showed that the sampling norms under consideration behave similarly with respect to several probability belief models. This result corroborates previous researchers’ frequent finding that participants are sensitive to questions' and answers' usefulness. However, this result does not directly address when the sampling norms make contradictory claims. Simulations were therefore conducted to address the frequency, and pervasiveness in different environments, of disagreements between the sampling norms.

Simulation 1.0, Multiple features. How often do any of the norms disagree with each other, and does the number of features relate to the frequency of disagreement? To address this, the Vuma scenario (described in the above review of Skov & Sherman, 1986, and Slowiaczek et al., 1992, and in Appendix A) was simulated, with P(glom)=P(fizo)=0.5, and random feature probabilities, such as P(hulaWorn | glom). (“Random probabilities” denotes pseudorandom numbers independently sampled from a uniform distribution between [0,1].) Ten thousand random trials were run for each number of features between 2 and 20. Each trial was analyzed to determine whether there was disagreement between diagnosticity, log diagnosticity, information gain-KL distance, and probability gain-impact on the relative usefulness of each feature. Number of disagreements increased monotonically with the number of features. Disagreements occurred in 7% of 2 feature trials, a majority of 6 feature trials, and more than 99% of 15 feature trials.

Simulations 1.1-1.3, Several environments. Is the existence of disagreements between sampling norms restricted to a particular environment? In each simulation, 1,000,000 random
trials were generated. Simulation 1.1 used random feature probabilities and random prior probabilities. Simulation 1.2 used equal prior probabilities, and random feature probabilities. Simulation 1.3 considered an environment where both features were “rare” (feature probabilities between 0 and 0.5), as subjects in hypothesis-testing tasks usually assume (Anderson & Sheu, 1995; McKenzie & Mikkelsen, 2000; McKenzie et al., 2001; Oaksford & Chater, 2003), but was otherwise identical to Simulation 1.1. Results showed that in each simulation, every possible type of pairwise disagreement (where one norm prefers Hula and another norm prefers Drink) occurred. Likewise, each simulation produced cases of disagreement with and without extreme feature values: having a feature probability close to 0 or 1 is not necessary for a disagreement to occur. In simulations 1.1 and 1.3, where P(glom) was random, sometimes both questions had zero probability gain. Simulation 1.3, with rare features, had results similar to Simulation 1.1. Together, these simulations show that in a variety of environments, using one norm leads to asking different questions than using another norm. Some cases of disagreement were qualitatively stronger than others, an issue addressed below.

Simulation 2: Cases of strongest disagreement

Could identification of cases of strong disagreement elucidate the differences between the sampling norms? This section describes a simulation to search for limiting cases.

Methods. A simulation automatically searched for cases of high pairwise disagreement strength ($DStr$, defined in Appendix B) between diagnosticity, log diagnosticity, information gain-KL distance, probability gain, and impact. Each optimization used fixed prior probabilities, specified by P(glom), and began with random feature probabilities, in which the two norms being compared disagreed about which feature was more useful. Optimizations to maximize the disagreement between all ten pairs (5 choose 2 = 10) of norms were run, for each P(glom)
between 0.50, 0.505, 0.51, … 0.995. The optimization procedure was allowed to find feature probabilities of 0, any number between 0.0001 and 0.9999, or 1. Each trial was repeated 10 times; feature probabilities in the trial with the highest DStr were recorded.

Results and discussion. Figure 1 shows the maximum obtained DStr as a function of P(glom), for each pair of norms. A surprising result, considering that some researchers have used diagnosticity and log diagnosticity interchangeably, is the consistently high disagreement between diagnosticity and log diagnosticity (dashed line at top of figure). In each of the trials in this particular optimization, diagnosticity's claims were strongly suboptimal with respect to all other sampling norms; log diagnosticity agreed with information gain-KL distance, probability gain, and impact. In all other optimizations where very high disagreement (DStr near 100) was observed, diagnosticity and log diagnosticity agreed with each other in each trial, but were suboptimal with respect to all other norms. In these trials diagnosticity and log diagnosticity were unduly influenced by the occasional presence of a certainty-inducing answer, which occurred because a feature probability was 1 or 0. Information gain-KL distance, probability gain, and impact had only moderate degrees of disagreement with each other, suggesting that they may be more closely related to each other (three lines in middle and bottom of figure).

Representative cases of disagreement are discussed below; Appendix B shows how patterns change as a function of P(glom). (Additional results are included in the supplementary material posted online.) In most of the individual cases discussed below, P(glom)=0.70; this prior led to high DStr in most optimizations (Figure 1, Appendix B). Where multiple optimizations, for example probability gain vs. diagnosticity, and probability gain vs. log diagnosticity, produced essentially identical feature probabilities, those optimizations are discussed simultaneously.

[insert Figure 1 about here]
Log_{10} diagnosticity vs. diagnosticity (Table B1). Illustrative trial where P(glom)=0.70: P(hulaWorn | glom)=0.9987, P(hulaWorn | fizo)=0.0013, P(drinksTea | glom)=0.0001, and P(drinksTea | fizo)=0.6202; DStr=99.68. Diagnosticity rates the Drink feature as much more useful than Hula; log_{10} diagnosticity rates Hula as much more useful than Drink. Testing the Hula feature leads to probability 0.9987 of correct guess (remaining uncertainty 0.0137 bit); testing the Drink feature leads to probability 0.8860 of correct guess (remaining uncertainty 0.4763 bit). Similar examples were observed in other limiting cases of disagreement between diagnosticity and log_{10} diagnosticity. In all of these cases, using diagnosticity to select questions is strongly suboptimal with respect to probability of correct guess (probability gain), reduction in uncertainty (information gain), and absolute change in beliefs (impact).

Information gain vs. diagnosticity; information gain vs. log_{10} diagnosticity; impact vs. diagnosticity; impact vs. log_{10} diagnosticity (Table B2). If a question has any possibility of completely eliminating a hypothesis, then even if that possibility is extremely remote, diagnosticity and log diagnosticity regard that question as infinitely useful. Illustrative trial for information gain vs. diagnosticity: P(glom)=0.70, P(hulaWorn | glom)=0.0001, P(hulaWorn | fizo)=0.9999, P(drinksTea | glom)=0.0001, and P(drinksTea | fizo)=0.0000. Hula leads to 99.99% probability of correct guess (probability gain 0.2999), and to uncertainty 0.0014 bit (information gain 0.8799 bit). Drink gives no improvement in probability of correct guess (probability gain 0), and almost no reduction in uncertainty (information gain 0.00004 bit). Yet the Drink question, with probability 7 in 100,000, results in the drinksTea answer, which provides conclusive evidence that the creature is a glom. Diagnosticity and log diagnosticity therefore consider the Drink question to be infinitely\textsuperscript{11} useful. Probability gain, information gain-KL distance, and impact all strongly prefer the Hula question. Essentially identical results
occurred throughout the optimizations in which information gain or impact was contrasted with diagnosticity or log diagnosticity.

*Probability gain vs. diagnosticity; probability gain vs. \( \log_{10} \text{diagnosticity} \) (Table B3).* Illustrative trial for probability gain vs. diagnosticity: \( P(\text{glom})=0.70, \) \( P(\text{hulaWorn} \mid \text{glom})=0.0001, P(\text{hulaWorn} \mid \text{fizo})=0.9999, P(\text{drinksTea} \mid \text{glom})=0.0914, \) and \( P(\text{drinksTea} \mid \text{fizo})=0.0000; \text{DStr}=97.48. \) Hula has probability gain 0.2999; Drink, 0. Hula has information gain 0.8799; Drink, 0.0343. Yet the Drink feature has infinite diagnosticity and \( \log_{10} \) diagnosticity. In all cases of these optimizations, diagnosticity and log diagnosticity agreed with each other, and were suboptimal with respect to information gain, impact, and probability gain. These optimizations’ results are similar in some respects to the previous example comparing information gain and diagnosticity. However, probability gain is zero for a wider range of feature probabilities than information gain and impact. In the present optimization that tends to result in more variable feature probabilities in the question that diagnosticity and \( \log_{10} \) diagnosticity prefer. (Had the present example contrasted information gain with diagnosticity, \( P(\text{drinksTea} \mid \text{glom}) \) would have been expected to be 0.0001, rather than 0.0914.)

*Information gain vs. probability gain (Table B4).* Recall that information gain generally prefers features with an extreme feature probability, especially features with an extreme feature probability given the working hypothesis. By contrast, probability gain prefers features with an extreme feature probability given the working hypothesis, but not extreme feature probabilities in general. In this optimization, information gain preferred a feature with an extreme feature probability given the alternate hypothesis, e.g. \( P(\text{hulaWorn} \mid \text{fizo})=0 \) or 1. Probability gain preferred a feature in which the more extreme of the two feature probabilities was paired with the working hypothesis (glom). Illustrative example where \( P(\text{glom})=0.70, \)
P(hulaWorn | glom)=0.5714, P(hulaWorn | fizo)=0.0000, P(drinksTea | glom)=0.9525, and P(drinksTea | fizo)=0.5587; DStr=58.04. Hula had probability gain zero; Drink had probability gain 0.0991. Information gain, however, was greater for Hula (0.2813 bit) than for Drink (0.1577 bit). Impact agreed with probability gain when P(glom) was between 0.50 and 0.58, and with information gain for more extreme values of P(glom). In most cases the feature preferred by information gain offered the possibility of a certain result, and was favored by diagnosticity and log diagnosticity.

*Information gain vs. impact (Table B5).* Information gain has a preference for extreme feature probabilities, especially extreme feature probabilities given the working hypothesis (glom where P(glom)>0.50). If feature difference is held constant, then impact has no preference between features with extreme feature probabilities given the working or alternate hypothesis, or without extreme feature probabilities altogether. This optimization gave each feature preferred by information gain (Hula) probability of 1 or 0 given the working hypothesis. Compared with the Hula features, the Drink features were given less extreme feature probabilities overall. To further minimize their information gain, the Drink features are asymmetric in the sense that the relatively extreme feature probability was paired with the alternate hypothesis (fizo). Illustrative example, where P(glom)=0.70: P(hulaWorn | glom)=1, P(hulaWorn | fizo)=0.6247, P(drinksTea | glom)=0.2770, and P(drinksTea | fizo)=0.7791; DStr=39.57. Information gain was 0.2213 for Hula, and 0.1604 for Drink; impact was 0.1576 for Hula, and 0.2109 for Drink. Probability gain was 0.1126 for Hula, and 0.0398 for Drink. In this optimization probability gain agreed with impact when P(glom) was between 0.5 and 0.58, and with information gain for more extreme P(glom) values.

*Probability gain vs. impact (Table B6).* Probability gain and impact are identical if
P(glom)=P(fizo)=0.5, but otherwise can disagree. Impact is a constant multiple of feature difference, for fixed P(glom), and always prefers the question with maximal difference in feature probabilities. For impact’s preferred feature (Hula), the optimization appears to have maximized feature difference, subject to the constraint that the feature have probability gain approximately zero. This was achieved by making the most extreme feature probability conditional on the alternate hypothesis, e.g. P(hulaWorn | fizo)=0 or 1. For the feature that probability gain prefers, the optimization found features with lower feature difference than the corresponding feature preferred by impact, but in which an extreme feature probability was conditioned on the working hypothesis, e.g. P(drinksTea | glom)=0 or 1, so as to maximize probability gain. Illustrative example where P(glom)=0.70: P(hulaWorn | glom)=0.5714, P(hulaWorn | fizo)=0, P(drinksTea | glom)=1, P(drinksTea | fizo)=0.6966; DStr=55.25. Hula has impact 0.2400; Drink, 0.1274. Hula has probability gain 0; Drink, 0.0910. In each trial of this optimization, information gain agreed with impact.

An experiment to separate sampling norms

Given that people may choose queries in a noisy manner (Hattori, 2002), an experiment to identify what norms best predict human queries should use cases of strong disagreement between norms. This section reports an experiment whose design was based on cases of maximal possible disagreement between norms, given equal priors, as identified by Simulation 2 (Appendix B).

Method. Subjects were undergraduate students in an introduction to cognitive science class at UCSD (N=151), who participated as part of class requirements. All subjects gave informed consent. A planet Vuma scenario was used; subjects were asked to rate the possible questions from most to least useful for determining whether a novel Vumian was a glom or fizo. Prior probabilities of glom and fizo were equal.12 Table 10 gives the feature probabilities of each
question, and each norm’s calculation of each question’s usefulness. A sample stimulus is given in Appendix C. The order of features with particular feature probabilities, and the order of features’ labels (Drink, Gurgle, etc.), both varied across subjects.

[insert Table 10 about here]

Results and discussion. Three subjects were excluded for not ranking all features. One subject gave all queries equal rank. Correlations between that subject’s data and each sampling norm are set to 0 in the analyses. The most common pattern (32% of subjects) was an exact match to information gain-KL distance. The next most common pattern (27%) was an exact match to probability gain-impact. No responses matched diagnosticity or log diagnosticity. Table 11 summarizes frequent ordering patterns, along with each pattern’s Spearman rank correlation with information gain, probability gain, diagnosticity, and log diagnosticity.

[insert Table 11 about here]

Two analyses were conducted. The first analysis addressed whether the number of responses consistent with each norm was consistent with assigning rank orders 1 through 4 at random. The probability of exactly matching a particular norm by chance, under this null hypothesis, is $1/4! = 1/16$. The number of subjects matching a particular norm, under this null hypothesis, is approximately normally distributed with mean 9.25, standard deviation 2.94. (Standard deviation is derived from the binomial variable with parameter 1/16, and $n=148$.) Significantly more subjects gave rankings in accord with information gain ($t(147)=13.2, p<0.0001$) and probability gain ($t(147)=10.4, p<0.0001$) than expected under the null hypothesis. No subjects responded according to diagnosticity or log diagnosticity, less than expected under the null hypothesis (each $t(147)= -3.1, p<0.01$). (All stated $p$ values are two tailed, and have been multiplied by 4 to correct for multiple tests.) The second analysis consisted of all 148 responses’ Spearman rank
correlations with each sampling norm (bottom row, Table 11). Average correlation with information gain-KL distance was 0.78; probability gain-impact, 0.69; log diagnosticity, -0.22; and diagnosticity, -0.41. These results strongly contradict claims that people choose queries according to diagnosticity or log diagnosticity.

The other norms make relatively similar predictions, and are not strongly differentiated from each other here. However, some points may be noted. Information gain-KL distance had the largest number of exact matches. Probability gain and impact, which made the same predictions (due to equal priors), were second. Subjects were not asked to explain their choices in this experiment. However, several pilot subjects reported using the feature difference strategy, in a scenario with unequal priors, which corresponds to impact. (Slowiaczek et al., 1992 found a similar result in a scenario with equal priors.) If the feature difference strategy is consistently used, then impact is a necessary component of a descriptive theory of human questions.

Theoretical problems with Bayesian diagnosticity and log diagnosticity

It is possible that an inquirer's subjective sense of queries' usefulness might correspond to diagnosticity or log diagnosticity. But that seems unlikely and normatively ill-advised, in part for the following reasons.

Disregard for priors if features are symmetric. Intuitively, it seems that if the inquirer already knows the true category or hypothesis, for instance because all creatures are known to be gloms, no question is useful (Lindley, 1956, p. 987), but if the inquirer is highly uncertain, many questions are useful. Consider the symmetric feature probability case, where

\[
P(\text{hulaWorn} \mid \text{glom}) = 1 - P(\text{hulaWorn} \mid \text{fizo}).
\]

Diagnosticity and \( \log_{10} \) diagnosticity rate the Hula question as equally useful, irrespective of whether gloms comprise 1%, 20%, 50%, or 99.9999% of the creatures on Vuma. The other sampling norms recognize that if the true category is known
in advance, every question is useless. This disregard for prior knowledge, in cases with symmetric feature probabilities, is an undesirable yet unavoidable consequence of using diagnosticity or log diagnosticity.

*Oversensitivity to occasional certainty: Features with multiple values.* This paper focused on a situation with binary features. What if answers (features) could take three or more values $q_j$? Perhaps a single fizo has a hard time hearing “Do you drink iced tea?” because of an injury to its auditory system, and answers “maybe” if a question is not clear. If occurrence of the maybe answer makes it certain that the creature is a fizo, then diagnosticity and log diagnosticity rate the question as infinitely useful. This holds even if the maybe answer is rare, occurring with probability $1/1,000,000$. The other norms are not unduly influenced by a certainty-inducing answer with rare occurrence.\(^{13}\)

*Log diagnosticity can be normatively inferior to diagnosticity.* Let $P(\text{glom})=0.99$, $P(\text{hulaWorn} \mid \text{glom})=0.99$, $P(\text{hulaWorn} \mid \text{fizo})=0.50$, $P(\text{drinksTea} \mid \text{glom})=0.97$, and $P(\text{drinksTea} \mid \text{fizo})=0.50$. Probability gain is zero for both questions. Log diagnosticity prefers Drink, which is suboptimal with respect to diagnosticity, information gain-KL distance, and impact. There are a range of cases like this in which diagnosticity and log diagnosticity contradict each other, and in which log diagnosticity makes the normatively inferior (as judged by information gain-KL distance, impact, and diagnosticity) claim.

*Multiple hypotheses/categories.* Fischoff and Beyth-Marom (1983, p. 243) stated that diagnosticity was defined in situations with multiple hypotheses, although they did not provide an operational definition; Oaksford and Chater (2003, p. 309) stated the contrary. A literature review conducted for the present paper failed to produce a single example calculation of a query’s diagnosticity, in a situation with more than two hypotheses. However, for the sake of
argument, an operational definition is provided here. (Generalization to cases with more than three categories, and definition of $\log_{10}$ diagnosticity++, are straightforward.) Note that what has been called the diagnosticity of a question, Hula, could just as easily be called the *pairwise diagnosticity* of Hula with respect to whether a creature is a glom or fizo, and denoted $\text{diagnosticity}_{\text{glom&fizo}}(\text{Hula})$. Now suppose that jevas, in addition to gloms and fizos, reside on Vuma. Define diagnosticity++ as the average of each pairwise diagnosticity:

$$\text{diagnosticity}^{++}(\text{Hula}) = \frac{1}{3} \left( \text{diagnosticity}_{\text{glom&fizo}}(\text{Hula}) + \text{diagnosticity}_{\text{glom&jeva}}(\text{Hula}) + \text{diagnosticity}_{\text{fizo&jeva}}(\text{Hula}) \right).$$

How would diagnosticity++ perform? To explore this, the diagnosticity++ of the medical tests from experiments 4-6 in Baron et al. (1988) was computed. Results showed that with the exception of those tests that can never change beliefs, irrespective of their outcome (and that all norms agree are useless), every test has infinite diagnosticity++. Diagnosticity++ is useless in this case, and in every case where each test has non-zero probability of eliminating a hypothesis.

*Does it matter?* In the real world, would using diagnosticity or log diagnosticity actually be problematic? Suppose one’s task were to identify the gender of a passerby, by inquiring about one of several features of interest: whether they have a beard, are wearing a dress, are wearing earrings, etc. Statistics were gathered from one natural environment, the UCSD campus in the afternoon, with each of about 500 passersby classified according to their gender (51% were male; 49% female) and several features (Table 12). What features are most useful, according to each sampling norm? The Hair length feature has maximal information gain-KL distance, probability gain, and impact. Asking about Hair length leads to 93% probability of correctly categorizing gender. The Skirt and Beard features have infinite diagnosticity and log diagnosticity, because 0% of males wore skirts and 0% of females had beards. Asking about Skirt or Beard leads, respectively, to only 52% or 59% probability of correct guess. Although the
wearsSkirt and hasBeard answers provide 100% certainty of the person’s gender in this population, those answers are infrequent. For a person, or seeing robot, to use diagnosticity or log diagnosticity to select queries in this natural environment would be exceptionally inefficient, with respect to all the other sampling norms. The other norms make reasonable claims, and differ from each other only slightly.

[insert Table 12 about here]

General discussion

Diagnosticity and log diagnosticity lack several useful properties that the other norms each possess, including (1) sensitivity to prior probabilities: if there is minimal uncertainty, no question has high usefulness; (2) being finite; and (3) equal applicability in situations with 2, 3, or 1,000,000 hypotheses or categories. Because diagnosticity and log diagnosticity lack these important properties, contradict this paper's experimental results, and appear unnecessary to explain other empirical data, there appears to be no further purpose for them in normative or descriptive theories of evidence acquisition.

In many evidence-gathering situations, where there is no particular external coercion shaping behavior, more than one sampling norm might reasonably apply. Several researchers explicitly make this point (Baron, 1985; Klayman & Ha, 1987; Klayman, 1987; Slowiaczek et al., 1992; Over & Jessop, 1998; Oaksford & Chater, 2003). Theoretical claims that human evidence seeking is adaptive (or that it is biased) would be bolstered by showing that multiple sampling norms agree on what questions are most useful.

A further issue is whether people actually use normative, versus heuristic, utilities. Various heuristic confirmatory or positive test strategies have been proposed (Skov & Sherman, 1986; Klayman & Ha, 1987, 1989; Gorman, Stafford & Gorman, 1987; Devine, Hirt, & Gehrke, 1990;
Slowiaczek et al., 1992; reviewed in Klayman, 1995). In some situations, strategies that reduce memory load (Costa-Gomes, Crawford, & Broseta, 2001) might also be used. These and other possibilities, including the sampling norms of the present paper, could be combined to form very flexible heuristic models. Most empirical data might then appear to be better fit by a heuristic model than by a sampling norm, because of the heuristic model's greater complexity. To avoid overfitting, future research comparing simple sampling norms with flexible heuristic models could explicitly balance model complexity with descriptive accuracy (Pitt, Myung, & Zhang, 2002).

Geman and Jedynak (2001) describe situations in which looking only one step into the future, as done in this paper, results in having to ask more questions on average than would be required if an optimal sequence of questions were planned in advance (also see Chernoff, 1959, 1972; Klauer, 1999). Unfortunately, planning an optimal series of questions requires knowledge of the individual features’ conditional dependence on each other, given the true category. For example, if a particular glom drinks gasoline, is he more likely to breathe fire than the average glom? Most tasks have not specified this information, or have not obtained sequences of questions, and are therefore unable to address whether subjects’ queries are sensitive to class-conditional dependencies. In a review of work on perceptual information integration (not involving active sampling), Movellan and McClelland (2002) found that people made appropriate use of features' level of class-conditional dependence. Whether people's queries make use of these intricate statistical relationships is an important issue for future research.

Appendix A: Example calculations of each sampling norm

Each sampling norm will be discussed in the context of the planet Vuma scenario (Skov & Sherman, 1986; Slowiaczek et al., 1992). The task is to discover whether a novel creature is a glom or fizo, by asking whether it possesses a particular binary feature, such as wearing a hula hoop or not, or drinking iced tea or not. The probability belief model is specified with five parameters. These parameters are listed here, together with specific example values: the prior probability that an individual creature is a glom, \( P(\text{glom}) = 0.70 \), and four feature probabilities, \( P(\text{hulaWorn} \mid \text{glom}) = 0.1 \), \( P(\text{hulaWorn} \mid \text{fizo}) = 0.9 \), \( P(\text{drinksTea} \mid \text{glom}) = 0.3 \), and \( P(\text{drinksTea} \mid \text{fizo}) = 0.5 \). Questions are answered truthfully; Bayes' theorem is used to update beliefs. For instance, if a hula hoop is worn:

\[
P(\text{glom} \mid \text{hulaWorn}) = \frac{P(\text{hulaWorn} \mid \text{glom}) \cdot P(\text{glom})}{P(\text{hulaWorn})} = \frac{0.1 \cdot 0.7}{0.34} \approx 0.21,
\]

where

\[
P(\text{hulaWorn}) = P(\text{hulaWorn} \mid \text{glom}) \cdot P(\text{glom}) + P(\text{hulaWorn} \mid \text{fizo}) \cdot P(\text{fizo})
= 0.1 \cdot 0.7 + 0.9 \cdot 0.3 = 0.34,
\]

by the Law of Total Probability.

(All knowledge to date becomes prior knowledge when calculating the usefulness of subsequent questions; for instance, if features have class-conditional dependencies, obtained answers may change feature probabilities in addition to \( P(\text{glom}) \) and \( P(\text{fizo}) \), as the General Discussion considers.) Is the Drink or Hula question more useful in this example? Each sampling norm gives its own means of calculating an individual answer's usefulness. However, all norms discussed in this paper define a question's usefulness as the expected usefulness of the individual answers:

\[
\text{usefulness(Hula)} = P(\text{hulaWorn}) \cdot \text{usefulness(hulaWorn)} + P(\text{hulaNotWorn}) \cdot \text{usefulness(hulaNotWorn)}
\]

Equations for the hulaWorn answer and the Hula question follow; specific values for the sample questions are given in Table A1.
**Diagnosticity**

\[
\text{diagnosticity}(\text{hulaWorn}) = \max \left( \frac{P(\text{hulaWorn} | \text{glom})}{P(\text{hulaWorn} | \text{fizo})} \cdot \frac{P(\text{hulaWorn} | \text{fizo})}{P(\text{hulaWorn} | \text{glom})} \right), \text{ and}
\]

\[
\text{diagnosticity}(\text{Hula}) = P(\text{hulaWorn}) \ast \text{diagnosticity}(\text{hulaWorn}) + P(\text{hulaNotWorn}) \ast \text{diagnosticity}(\text{hulaNotWorn}).
\]

**Log₁₀ diagnosticity**

\[
\text{log}_{10}\text{ diagnosticity}(\text{hulaWorn}) = \log_{10} \max \left( \frac{P(\text{hulaWorn} | \text{glom})}{P(\text{hulaWorn} | \text{fizo})} \cdot \frac{P(\text{hulaWorn} | \text{fizo})}{P(\text{hulaWorn} | \text{glom})} \right), \text{ and}
\]

\[
\text{log}_{10}\text{ diagnosticity}(\text{Hula}) = P(\text{hulaWorn}) \ast \text{log}_{10}\text{ diagnosticity}(\text{hulaWorn}) + P(\text{hulaNotWorn}) \ast \text{log}_{10}\text{ diagnosticity}(\text{hulaNotWorn}).
\]

**Information gain**

The information gain of the answer hulaWorn,

\[
\text{information gain}(\text{hulaWorn}) = H(\text{Species}) - H(\text{Species} | \text{hulaWorn}), \text{ where}
\]

\[
H(\text{Species}) = P(\text{glom}) \ast \log_{2} \frac{1}{P(\text{glom})} + P(\text{fizo}) \ast \log_{2} \frac{1}{P(\text{fizo})}, \text{ and}
\]

\[
H(\text{Species} | \text{hulaWorn}) = P(\text{glom} | \text{hulaWorn}) \ast \log_{2} \frac{1}{P(\text{glom} | \text{hulaWorn})} + P(\text{fizo} | \text{hulaWorn}) \ast \log_{2} \frac{1}{P(\text{fizo} | \text{hulaWorn})}.
\]

The information gain of the Hula question, the mutual information between Hula and Species,

\[
I(\text{Hula, Species}) = H(\text{Species}) - H(\text{Species} | \text{Hula}), \text{ where the conditional entropy,}
\]

\[
H(\text{Species} | \text{Hula}) = P(\text{hulaWorn}) \ast H(\text{Species} | \text{hulaWorn}) + P(\text{hulaNotWorn}) \ast H(\text{Species} | \text{hulaNotWorn}).
\]

**Kullback Liebler (KL) distance**
\[
KL \text{ distance}(hulaWorn) = P(glom \mid hulaWorn) \log_2 \frac{P(glom \mid hulaWorn)}{P(glom)} + P(fizo \mid hulaWorn) \log_2 \frac{P(fizo \mid hulaWorn)}{P(fizo)},\text{ and}
\]

\[
KL \text{ distance}(Hula) = P(hulaWorn) \cdot KL \text{ distance}(hulaWorn) + P(hulaNotWorn) \cdot KL \text{ distance}(hulaNotWorn).
\]

**Probability gain**

\[
\text{probabilityGain}(hulaWorn) = \max( P(fizo\mid hulaWorn), P(glom\mid hulaWorn) ) - \max( P(glom), P(fizo) ).
\]

\[
\text{probabilityGain}(Hula) = P(\text{CorrectGuess} \mid Hula) - P(\text{CorrectGuess}), \text{ where}
\]

\[
P(\text{CorrectGuess}) = \max(P(glom), P(fizo)), \text{ and}
\]

\[
P(\text{CorrectGuess} \mid Hula) = P(hulaWorn) \cdot \max(P(glom \mid hulaWorn), P(fizo \mid hulaWorn)) + P(hulaNotWorn) \cdot \max(P(glom \mid hulaNotWorn), P(fizo \mid hulaNotWorn))
\]

**Impact**

From the definition in the text,

\[
\text{impact}(hulaWorn) = 0.5 \cdot \text{abs}(P(glom \mid hulaWorn) - P(glom)) + 0.5 \cdot \text{abs}(P(fizo \mid hulaWorn) - P(fizo)).
\]

Because \(P(fizo \mid hulaWorn)=1-P(glom \mid hulaWorn)\), and \(P(fizo)=1-P(glom)\),

\[
\text{impact}(hulaWorn) = \text{abs}(P(glom \mid hulaWorn) - P(glom)).
\]

If a probability model has two categories, the impact of a question is a constant multiple of the difference in feature probabilities (see the footnote in the introduction of impact, in the text):

\[
\text{impact}(Hula) = 2 \cdot P(glom) \cdot P(fizo) \cdot \text{abs}(P(hulaWorn \mid glom) - P(hulaWorn \mid fizo)).
\]

[insert Table A1 about here]
Appendix B: limiting cases of disagreement between norms

This appendix gives several limiting cases of disputes between each pair of norms, as obtained in Simulation 2. Each optimization shows results for several prior probabilities, to illustrate the systematic relationship of feature probabilities to the prior $P(\text{glom})$. Each table (B1-B6) gives results for an optimization comparing one pair of norms. Tables are organized such that one norm prefers the "Hula" question, and the other norm prefers the "Drink" question, as noted.

**Precise definition of DStr and Preference Strength.** Disagreement Strength ($DStr$) is defined to be high when one norm strongly prefers one particular question, and another norm strongly prefers the other question. $DStr$, therefore, requires a measure of each individual norm’s strength of preference between Drink and Hula. The absolute value of the difference in usefulness of Hula and Drink, as measured by each norm, was computed in each of 100,000 random trials, in which $P(\text{glom})$, $P(\text{wearsHula} | \text{glom})$, etc., were all random probabilities. For probability gain, cases where both features had probability gain zero, and were therefore tied, were excluded; no other ties occurred. Endpoints to the distributions underlying each norm’s strength of preference were added where they exist. In a novel trial, a particular norm’s degree of preference is quantified as a percentile of the set of 100,000 previously observed differences in the usefulness of Hula and Drink. Linear interpolation was used so that $DStr$ would be continuously valued. $DStr$ is the geometric mean (the square root of the product) of two norms’ strengths of (contrary) preferences.

[insert tables B1-B6 about here]
Appendix C: sample stimulus from Vuma experiment

Imagine you are visiting the planet Vuma. There are 1 million creatures on Vuma; 50% of them are Gloms, and 50% are Fizos. All creatures are invisible to the human eye, so you cannot learn about them by looking at them, but only by asking them questions.

Suppose you have just met a creature from Vuma. Your job is to tell which of the two kinds of creatures it is. The table below gives information about the percent of Gloms, and the percent of Fizos, with certain characteristics. (The characteristics are listed in a random order.)

<table>
<thead>
<tr>
<th>Characteristic</th>
<th>drinks tea</th>
<th>wears a hula hoop</th>
<th>plays harmonica</th>
<th>gurgles a lot</th>
</tr>
</thead>
<tbody>
<tr>
<td>proportion of Gloms</td>
<td>30%</td>
<td>99%</td>
<td>1%</td>
<td>70%</td>
</tr>
<tr>
<td>proportion of Fizos</td>
<td>0.01%</td>
<td>100%</td>
<td>99%</td>
<td>30%</td>
</tr>
</tbody>
</table>

Imagine that to help you find out the identity of the creature, you could ask it one yes or no question, about one of its characteristics. For instance, if “swims fast” were a characteristic, you could ask “Do you swim fast?” The creature answers truthfully.

Considering the information given, which of the possible questions would be most useful to help you learn whether the creature is a Glom or Fizo? Please rank the questions below, putting a “1” in the box beside the most useful question, a “2” in the box beside the next-most-useful question, and so on. If two questions are equally useful, give them the same rank.

<table>
<thead>
<tr>
<th>Question</th>
<th>Rank</th>

</thead>
<tbody>
<tr>
<td>Do you drink tea?</td>
<td></td>
</tr>
<tr>
<td>Do you wear a hula hoop?</td>
<td></td>
</tr>
<tr>
<td>Do you play harmonica?</td>
<td></td>
</tr>
<tr>
<td>Do you gurgle a lot?</td>
<td></td>
</tr>
</tbody>
</table>
Footnotes

1 Pseudodiagnosticity papers (Doherty, Mynatt, Tweney, & Schiavo, 1979; Doherty, Schiavo, Tweney, & Mynatt, 1981; Beyth-Marom & Fischoff, 1983; Doherty, Chadwick, Garavan, Barr, & Mynatt, 1996; Maggi, Butera, Legrenzi, & Mugny, 1998) also use diagnosticity as a sampling norm. In a typical experiment subjects are given $d_1$ (datum1) and $d_2$ and are trying to determine whether $h_1$ or $h_2$ is the correct hypothesis. They may select two of four possible pieces of information: $P(d_1|h_1)$, $P(d_1|h_2)$, $P(d_2|h_1)$, or $P(d_2|h_2)$. The normatively correct behavior, which makes it possible to calculate posterior probabilities, is to select $P(d_1|h_1)$ and $P(d_1|h_2)$, or $P(d_2|h_1)$ and $P(d_2|h_2)$. Subjects frequently make other selections, which is nonnormative irrespective of the sampling norm used. Unfortunately, these empirical data do not discriminate the relative plausibility of different sampling norms as descriptive models.

2 Proof of equivalence of heuristic feature difference maximization strategy and impact sampling norm, where there are two categories $c_1$ and $c_0$, and a question $Q$ with possible answers $q_1$ and $q_2$. If $P(q_1|c_1)>P(q_1|c_0)$, then impact($Q$)

$$= P(q_1)*\text{impact}(q_1) + P(q_2)*\text{impact}(q_2)$$

$$= P(q_1)*\text{abs}[ P(c_1|q_1) - P(c_1) ] + P(q_2)*\text{abs}[ P(c_1|q_2) - P(c_1) ], \text{ because there are two } c_i,$$

$$= P(q_1)*[ P(c_1|q_1) - P(c_1) ] + P(q_2)*[ P(c_1) - P(c_1|q_2) ], \text{ because } P(q_1|c_1)>P(q_1|c_0),$$

$$= P(q_1)*P(c_1|q_1) - P(c_1)*P(q_1) + P(c_1)*P(q_2) - P(q_2)*P(c_1|q_2)$$

$$= P(c_1)*P(q_1|c_1) - P(c_1)*P(q_1) + P(c_1)*P(q_2) - P(c_1)*P(q_2|c_1)$$

$$= P(c_1)*[P(q_1|c_1) - P(q_1) + P(q_2) - P(q_2|c_1) ]$$

$$= P(c_1)*[P(q_1|c_1) - P(q_1) + (1-P(q_1)) - (1-P(q_1|c_1)) ],$$

because $P(q_1) = 1-P(q_2)$; $P(q_2|c_1) = 1-P(q_1|c_1)$,

$$= 2*P(c_1)*[ P(q_1|c_1) - P(q_1) ]$$

$$= 2*P(c_1)*[P(q_1|c_1) - P(c_1)*P(q_1|c_1) - P(c_0)*P(q_1|c_0)], \text{ by Law of Total Probability,}$
\[= 2 \times P(c_1) \times \left[ (1 - P(c_1)) \times P(q_i | c_1) - P(c_0) \times P(q_i | c_0) \right] \]

\[= 2 \times P(c_1) \times \left[ P(c_0) \times P(q_i | c_1) - P(c_0) \times P(q_i | c_0) \right], \text{ because } P(c_0) = 1 - P(c_1) \]

\[= 2 \times P(c_1) \times P(c_0) \times \left[ P(q_i | c_0) - P(q_i | c_1) \right] \]

By a similar derivation, if \( P(q_i | c_1) > P(q_i | c_0) \), then

\[\text{impact}(Q) = 2 \times P(c_1) \times P(c_0) \times \left[ P(q_i | c_0) - P(q_i | c_1) \right].\]

In both cases,

\[\text{impact}(Q) = 2 \times P(c_1) \times P(c_0) \times \text{abs} \left[ P(q_i | c_0) - P(q_i | c_1) \right].\]

3 Nick Chater (personal communication, 2005) raised this final issue.

4 If reducing the number of possible diseases improves treatment, irrespective of the true disease, probability gain might not be uniquely justified. Shanks, Tunney, and McCarthy (2002), on a two arm bandit task that did not involve active sampling, found that some subjects did seek to maximize average winnings. One could imagine a modified task that includes asking questions, where probability gain is uniquely compatible with the goal of maximizing average winnings.

5 In experiment 5 joint probabilities of each disease and each test, for instance that 32% of patients have disease 1 and a positive result from test A, were given. A set of conditional probabilities uniquely implies a set of joint probabilities, and vice versa.

6 Some research on the abstract selection task (Oaksford & Chater, 1998, 2003; Hattori, 2002) has reported information gain values scaled to sum to 1. The present paper reports non-normalized values; normalized values give the same ordering.

7 The present analysis fixed \( P(\text{dependence hypothesis}) = 0.5 \) and \( P(\text{error}) = 0.1 \), like Oaksford and Chater (2003, henceforth “OC2003”). But whereas OC2003 optimized \( P(A) \) and \( P(2) \) to fit data from each of several dozen experiments in the literature, the present analysis fixed
P(A)=0.22 and P(2)=0.27, to match the mean best fit parameters reported by OC2003. For each experiment, OC2003 used a logistic function to transform the information gain of each card into a probability of selection, as proposed by Hattori (2002). A further step in analysis of the selection task would be to replicate OC2003’s optimizations, finding the best fit parameters of P(A) and P(2) for each sampling norm, for each of the several dozen experiments OC2003 fit. Those results, for instance goodness of fit in each experiment, and number of experiments in which a model is rejected, could potentially speak to the relative descriptive plausibility of each sampling norm, even without overt disagreements on the ordering of the cards' usefulness.

8 In one of Inhelder and Piaget’s (1955/1958) studies subjects experimented with string length, weight on the string, etc., to learn what variables control the movement of a pendulum. Scientific reasoning research (Wason, 1960; Klahr, 2000; Kuhn, Amsel, & O'Loughlin, 1988, pp. 161-183; Kuhn, 1989, 2002; Zimmerman, 2000) frequently uses similarly rich tasks. Another related area is contingency, the degree to which one variable predicts another variable's occurrence later in time (Jenkins & Ward, 1965; Allan, 1993; Anderson & Sheu, 1995).

9 McKenzie and Mikkelsen (in press) did not specify prior probabilities of \( h_1 \) and \( h_0 \). The diagnosticity and log diagnosticity of an observation (answer \( q_j \)) is independent of priors; e.g. \( \log_2 \text{diagnosticity}(A)=2.46 \), irrespective of whether \( P(h_1)=P(h_2)=0.5 \), or \( P(h_1)=0.9999 \) and \( P(h_2)=0.0001 \). As the other norms are sensitive to priors, equal priors of \( h_1 \) and \( h_0 \) were used.

10 Methods and results are briefly described here; complete details on the design of the simulations and results are included in the supplementary material posted online, and at http://www.jonathandnelson.com.

11 Strict formalists may state that diagnosticity(Drink) is undefined. But clearly,

\[
\lim_{P(\text{drink} | \text{fizz}) \to 0^+} \text{diagnosticity(Drink)} = \infty.
\]

This difficulty stems from the definition of diagnosticity
and log diagnosticity. Features, like $P(\text{hasDNA} \mid \text{human})$, can have probability 0 or 1.

12 A pilot experiment with unequal prior probabilities of glom and fizo was conducted. Several subjects indicated that they had forgotten that priors were not equal when rating the questions. Because of this possible confound, and because of the default assumption that priors are equal (Fox & Rottenstreich, 2003), equal prior probabilities were used. Impact and probability gain are identical in this two category, equal prior probability case.

13 A further note is that reinforcement learning researchers (Kearns & Singh, 2002, p. 211) have found that learning an unknown probability model within a finite time is not possible if rewards can be infinite.
Figure 1

Simulation 2 results. Strength of limiting cases of disagreement between pairs of sampling norms, for different prior probabilities

</tr>
</tbody>
</table>

*Note.* Prior probabilities of diseases A, B, and C, were 0.64, 0.24, and 0.12, respectively. Baron et al. stated that most subjects rated tests 1 and 11 zero, but did not report subjects’ ratings of those tests. Subjects’ ratings, and the conditional probabilities of a positive test given each disease, are adapted from Table 5 in “Heuristics and biases in diagnostic reasoning: II. Congruence, information, and certainty,” by J. Baron, J. Beattie, and J. C. Hershey, 1988, *Organizational Behavior and Human Decision Processes, 42(1)*, p. 106. Copyright Elsevier; adapted with permission.
Table 7

*Correlation between three sampling norms and subjects' average ratings in Baron et al.'s (1988) study*

<table>
<thead>
<tr>
<th>Experiment</th>
<th>4</th>
<th>5</th>
<th>6</th>
</tr>
</thead>
<tbody>
<tr>
<td>Probability gain</td>
<td>0.84</td>
<td>0.91</td>
<td>0.83</td>
</tr>
<tr>
<td>Information gain</td>
<td>0.89</td>
<td>0.86</td>
<td>0.94</td>
</tr>
<tr>
<td>Impact</td>
<td>0.89</td>
<td>0.88</td>
<td>0.81</td>
</tr>
</tbody>
</table>

Note. Correlations exclude tests 1 and 11, in experiments 5 and 6, for which Baron et al. (1988) did not report subjects’ ratings. Correlations use Pearson's $r$. A similar pattern, with slightly lower correlation values, results if Spearman's rank correlation is used.
Table 8

*Cards' usefulness on the selection task*

<table>
<thead>
<tr>
<th></th>
<th>$A (P)$</th>
<th>$2 (Q)$</th>
<th>$3 (\text{not-}Q)$</th>
<th>$K (\text{not-}P)$</th>

</tbody>
</table>

*Note.* \(P(\text{glom})=0.70, P(\text{wearsHula} \mid \text{glom})=0.1, P(\text{wearsHula} \mid \text{fizo})=0.9,\)
\(P(\text{drinksTea} \mid \text{glom})=0.3, \text{and } P(\text{drinksTea} \mid \text{fizo})=0.5.\) Individual answers can have negative information gain or probability gain, as drinksTea illustrates. Questions’ usefulness is nonnegative irrespective of which sampling norm is used. The Drink question has probability gain zero because it does not improve probability of correct guess. Information gain and KL distance are equivalent when evaluating questions, but not individual answers, as shown.
### Table B1

*Log diagnosticity (prefers Hula) vs. diagnosticity (prefers Drink)*

<table>

<td>99.99 0.01</td>
<td>99.99 100.00</td>
<td>60.64</td>
<td>-100.00</td>
</tr>
</tbody>
</table>

*Note.* Results for impact vs. diagnosticity, information gain vs. log diagnosticity, and impact vs. log diagnosticity are not presented separately, because each of those optimizations produced feature probabilities that were virtually identical to the results for information gain vs. diagnosticity. DStr values for information gain vs. log diagnosticity were essentially identical to those for information gain vs. diagnosticity. DStr values for impact vs. diagnosticity, and impact vs. log diagnosticity, follow a qualitatively similar pattern; those values can be approximated from the strengths of each norm’s preference in Table B2.
Table B3

*Probability gain (prefers *Hula*) vs. *diagnosticity (prefers Drink)*

<table>
<thead>
